Abstract

Even in the absence of a sizable tensor contribution, a B-mode polarization can be generated because of the competition between a pseudo-scalar background and pre-decoupling magnetic fields. By investigating the dispersion relations of a magnetoactive plasma supplemented by a pseudo-scalar interaction, the total B-mode polarization is shown to depend not only upon the plasma and Larmor frequencies but also on the pseudo-scalar rotation rate. If the (angular) frequency channels of a given experiment are larger than the pseudo-scalar rotation rate, the only possible source of (frequency dependent) B-mode autocorrelations must be attributed to Faraday rotation. In the opposite case the pseudo-scalar contribution dominates and the total rate becomes, in practice, frequency-independent. The B-mode cross-correlations can be used, under certain conditions, to break the degeneracy by disentangling the two birefringent contributions.

In the Λ CDM paradigm¹ a potential candidate for the B-mode polarization are the tensor modes of the geometry inducing a frequency-independent polarization of the Cosmic Microwave Background (CMB in what follows). By *frequency-independent signal* we mean that different observational channels measure angular power spectra with the same amplitude. In the opposite case the angular power spectra will effectively depend upon the (angular) frequency of observation. The WMAP 5-yr data [1] constrain the presence of a B-mode and, indirectly, r_T , i.e. the ratio of the tensor power spectrum over the scalar power spectrum [1]. A further (frequency independent) source of B-mode polarization is cosmic shear (see e.g. [2]). Diverse data sets (such as the ones of Quad and Capmap [3]) impose concurrent limits on the B-mode polarization. Forthcoming experiments are expected to improve the present status of the observations by reaching into the region $r_T < 0.2$.

The only frequency-dependent signal investigated so far is provided by the Faraday effect which is a distinctive feature of magnetized plasmas in different contexts [4]. Large-scale magnetic fields present prior to the equality time are known to impact both on the temperature autocorrelations as well as on the polarization observables [5]. It has been recently shown, within a dedicated numerical approach [6], that the Faraday rotation signal induced by a pre-decoupling magnetic field can overwhelm the B-mode polarization induced by the standard tensor contribution [7].

The B-mode autocorrelations might not be always sufficient to infer the presence of a pre-equality magnetic field². In short, the idea is the following. Consider a set-up where the pre-equality plasma is birefringent because of the concurrent presence of a pseudo-scalar background field, be it σ , and of a large-scale magnetic field. Absent any pseudo-scalar background, the rotation rate would scale with the square of the wavelength [4] of the observational channel. In the presence of a pseudo-scalar field the dispersion relations can be generalized and the total rotation rate will have, both, a magnetic and a pseudo-scalar contribution. The purpose of this paper is to compute the B-mode polarization generated by the competition of the two aforementioned effects and to scrutinize if (and when) the two effects can be, at least partially, disentangled. The essentials of the problem at hand are usefully introduced in terms of the electromagnetic part of the action

$$S_{\text{em}} = -\frac{1}{16\pi} \int d^4x \sqrt{-g} \left[F_{\mu\nu} F^{\mu\nu} - \frac{\beta\sigma}{M} F_{\mu\nu} \tilde{F}^{\mu\nu} + 16\pi j^\nu A_\nu \right] \quad (1)$$

where $g = \det g_{\mu\nu}$ and $g_{\mu\nu} = a^2(\tau)\eta_{\mu\nu}$; $F_{\mu\nu}$ is the electromagnetic field strength; $\tilde{F}^{\mu\nu} =$

¹The Λ refers to the dark energy component (assumed to be in the form of a putative cosmological constant). The CDM refers to the (cold) dark matter contribution. In what follows the cosmological parameters will be fixed to the best fit of the WMAP-5yr data alone, i.e. $(\Omega_{b0}, \Omega_{c0}, \Omega_\Lambda, h_0, n_s, \epsilon) = (0.0441, 0.214, 0.742, 0.719, 0.963, 0.087)$. In the latter string of parameters Ω_X denotes the critical fraction of a given species, h_0 fixes the present value of the Hubble rate; n_s is the spectral index of curvature perturbations and ϵ is the reionization optical depth.

²Following the established terminology the B-mode autocorrelations are denoted by BB. With similar notation we will talk about the TT, TE, EE angular power spectra meaning, respectively, the autocorrelations of the temperature, the autocorrelations of the E-mode and their mutual cross-correlations.

$\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}/(2\sqrt{-g})$ is the dual field strength in curved space-times. In Eq. (1) β is a coupling constant and M a typical mass scale which may take specific values, for instance, in a given scenario [8]. In Eq. (1) j^ν denotes the electromagnetic current which can be specified in terms of the charge carriers (i.e. electrons and ions) as $j^\nu = j_i^\nu + j_e^\nu = e(\tilde{n}_i u_i^\nu - \tilde{n}_e u_e^\nu)$ (recall that, for both species, $g_{\mu\nu}u_{e,i}^\mu u_{e,i}^\nu = 1$). The relevant set of equations can then be written, for brevity, in their covariant form and they are

$$\nabla_\mu F^{\mu\nu} = 4\pi j^\nu + \frac{\beta}{M} \nabla_\mu \sigma \tilde{F}^{\mu\nu}, \quad \nabla_\mu \tilde{F}^{\mu\nu} = 0, \quad (2)$$

$$\nabla_\mu (T_e^{\mu\nu} + T_i^{\mu\nu} + T_{\text{EM}}^{\mu\nu}) = 0, \quad T_{e,i}^{\mu\nu} = \rho_{e,i} u_{e,i}^\mu u_{e,i}^\nu, \quad (3)$$

where $T_{\text{EM}}^{\mu\nu}$ is the energy-momentum tensor of the electromagnetic field and $\rho_{e,i}$ denote the energy density of electrons and ions. Note that ∇_μ (i.e. the covariant derivative associated with the space-time geometry) does not only depend upon the scale factor but also upon the inhomogeneities. Equation (3) summarizes schematically the evolution equations of charged species whose governing equations can be more appropriately derived from the Vlasov-Landau equations in curved space (or from their lowest moments). While electrons and ions are coupled through Coulomb scattering, the electron-ion fluid is coupled to the photon background. The plasma contains a large-scale magnetic field whose Fourier amplitudes satisfy

$$\langle B_i(\vec{k}, \tau) B_j(\vec{p}, \tau) \rangle = \frac{2\pi^2}{k^3} P_B(k) P_{ij}(k) \delta^{(3)}(\vec{k} + \vec{p}), \quad P_B = A_B \left(\frac{k}{k_L} \right)^{n_B-1} \quad (4)$$

where $k^2 P_{ij}(k) = (k^2 \delta_{ij} - k_i k_j)$; A_B is the amplitude of the magnetic power spectrum at the (comoving) magnetic pivot scale k_L (equal to 1 Mpc^{-1} in the forthcoming numerical examples). The magnetic field is inhomogeneous over typical length-scales which are of the order of the Hubble radius r_H . The Larmor radius of the electrons, on the contrary, is $r_L \simeq \mathcal{O}(v_{\text{th}}/\overline{\omega}_{\text{Be}}) \ll r_H$ where $\overline{\omega}_{\text{Be}}$ is the (comoving) Larmor frequency and $v_{\text{th}} \simeq \sqrt{T_e/m_e}$ is the thermal velocity of the electrons. For a comoving field strength $\mathcal{O}(\text{nG})$ the Larmor radius is roughly eight orders of magnitude smaller than the Hubble radius. The guiding centre approximation (originally due to Alfvén [9]) can be then applied. The charged particles orbiting around the magnetic field lines will see, in practice, a constant field up to drift corrections (going as $[T_e(\vec{B} \times \vec{\nabla})B]/(eB^3)$ where $B = |\vec{B}|$) and curvature corrections (going as $[T_e \vec{B} \times (\vec{B} \cdot \vec{\nabla}) \vec{B}]/(eB^4)$) which are, however, negligible when the scale of (spatial) variation of the magnetic background is much larger than the gyration radius of the charge carriers. As discussed in [8] the dispersion relations can be derived by studying the propagation of the electromagnetic waves in a magnetoactive plasma at finite density. By writing Eqs. (2)–(3) in their explicit form the compatibility of the system can be ensured if $\det \mathcal{A}_{ij} = 0$ where $\mathcal{A}_{ij}$ is given by

$$\mathcal{A}_{ij} = k^2(\delta_{ij} - \hat{k}_i \hat{k}_j) - \overline{\omega}^2 \bar{\epsilon}_{ij}(\overline{\omega}, \alpha) + i \frac{\beta}{M} \sigma' \epsilon_{mij} k^m. \quad (5)$$

In Eq. (5) $\bar{\epsilon}_{ij}(\overline{\omega}, \alpha)$ is the dielectric tensor and σ' denotes a derivation with respect to the conformal time coordinate τ . By requiring that $\det \mathcal{A}_{ij} = 0$ and by setting the comoving

wavenumbers in such a way that $k_x = 0$ and $k_y = k \sin \vartheta$ and $k_z = k \cos \vartheta$ the standard form of the Appleton-Hartree equation can be easily recovered and it is [8]

$$\begin{aligned} & \sin^2 \vartheta \left\{ \left(\frac{1}{\epsilon_{\parallel}} - \frac{1}{n^2} \right) \left[\frac{1}{n^2} - \frac{1}{2} \left(\frac{1}{\epsilon_-} + \frac{1}{\epsilon_+} \right) \right] + \frac{\bar{\omega}_\sigma^2}{2n^2 \bar{\omega}^2} \left(\frac{1}{\epsilon_-} + \frac{1}{\epsilon_+} \right) \right. \\ & - \left. \cos^2 \vartheta \left[\left(\frac{1}{n^2} - \frac{1}{\epsilon_-} \right) \left(\frac{1}{n^2} - \frac{1}{\epsilon_+} \right) - \frac{\bar{\omega}_\sigma^2}{n^2 \omega^2 \epsilon_+ \epsilon_-} \right] + \frac{\bar{\omega}_\sigma}{n^3 \bar{\omega}} \left(\frac{1}{\epsilon_-} - \frac{1}{\epsilon_+} \right) \cos \vartheta \right\} = 0, \end{aligned} \quad (6)$$

where $\alpha = i\mathcal{H}/\bar{\omega}$, $\mathcal{H} = a'/a$ and $n = k/\bar{\omega}$ is the refractive index. Denoting with $\bar{\omega}_{\text{pe},i}$ the comoving plasma frequencies for electrons and ions and with $\bar{\omega}_{\text{Be},i}$, the corresponding gyration frequencies $\epsilon_{\pm}(\bar{\omega}, \alpha)$ and $\epsilon_{\parallel}(\bar{\omega}, \alpha)$ are

$$\epsilon_{\pm}(\bar{\omega}, \alpha) = \epsilon_1 \pm \epsilon_2 = 1 - \frac{\bar{\omega}_{\text{pi}}^2}{\bar{\omega}[\bar{\omega}(\alpha + 1) \mp \bar{\omega}_{\text{Bi}}]} - \frac{\bar{\omega}_{\text{pe}}^2}{\bar{\omega}[\bar{\omega}(\alpha + 1) \pm \bar{\omega}_{\text{Be}}]}, \quad (7)$$

$$\epsilon_{\parallel}(\bar{\omega}, \alpha) = 1 - \frac{\bar{\omega}_{\text{pi}}^2}{\bar{\omega}^2(1 + \alpha)} - \frac{\bar{\omega}_{\text{pe}}^2}{\bar{\omega}^2(1 + \alpha)}. \quad (8)$$

The frequency $\bar{\omega}_\sigma = \beta\sigma'/M$ measures the rate of variation of the polarization because of the presence of the pseudo-scalar background. If σ is not homogeneous the dispersion relations will have a different form. According to Eq. (6) the refractive indices for electromagnetic propagation along the magnetic field (i.e. $\vartheta = 0$) can be deduced from

$$\left(n^2 - \frac{\omega_\sigma}{\omega} n - \epsilon_+ \right) \left(n^2 + \frac{\omega_\sigma}{\omega} n - \epsilon_- \right) = 0, \quad \vartheta = 0. \quad (9)$$

In the orthogonal direction the dispersion relations lead to the so-called ordinary and extraordinary plasma waves which are, however, not excited because of the minute values of the (comoving) plasma and Larmor frequencies for the electrons:

$$\bar{\omega}_{\text{Be}} = 0.01759 \left(\frac{\hat{n} \cdot \vec{B}}{\text{nG}} \right) \text{ Hz}, \quad \bar{\omega}_{\text{pe}} = 28.5 \left(\frac{h_0^2 \Omega_{\text{b0}}}{0.02273} \right)^{1/2} \text{ Hz}. \quad (10)$$

Indeed $\bar{\omega}_{\text{max}} > \bar{\omega}_{\text{pe}} \gg \bar{\omega}_{\text{Be}}$ where $\bar{\omega}_{\text{max}} = 2\pi\bar{\nu}_{\text{max}}$ and $\bar{\nu}_{\text{max}} = 222.617 \text{ GHz}$ corresponds to the maximum of the CMB spectral energy density. The rotation rate experienced by the linearly polarized CMB travelling parallel to the magnetic field direction is

$$\mathcal{F}(\hat{n}) = \frac{d\Phi}{d\tau} = \frac{\bar{\omega}}{2c} \left[\frac{\bar{\omega}_\sigma}{\bar{\omega}} + \sqrt{\frac{1}{4} \left(\frac{\bar{\omega}_\sigma}{\bar{\omega}} \right)^2 + \epsilon_+(\bar{\omega}, \alpha)} - \sqrt{\frac{1}{4} \left(\frac{\bar{\omega}_\sigma}{\bar{\omega}} \right)^2 + \epsilon_-(\bar{\omega}, \alpha)} \right]. \quad (11)$$

Since $\omega_\sigma \propto \sigma'$ the contribution to the rate can be, in principle, either positive or negative. This will affect the sign of the cross-correlations (e.g. the TB and EB angular power spectra). If $\bar{\omega} < \bar{\omega}_\sigma$, the shift in the polarization plane of the CMB will essentially be independent upon the channel of observation³. In the opposite case (i.e. $\bar{\omega} > \bar{\omega}_\sigma$) the magnetized and the pseudo-scalar contribution concur in determining the total amount of rotation and, ultimately, the various polarization observables, i.e., according to Eq. (11)

Figure 1: The angular power spectra of the B-mode autocorrelations (plot at the left) and the absolute values of the cross-correlations (plot at the right) are reported in the case when the pseudo-scalar background and the magnetized background are simultaneously present. The Λ CDM parameters have been chosen in accordance with the best fit to the WMAP5-yr data alone [1].

$\psi(\hat{n}, \tau) = \Phi_\sigma(\tau) + \Phi_{\text{Faraday}}(\hat{n}, \tau)$. The B-mode polarization induced by the magnetoactive plasma in the presence of a pseudo-scalar background can be computed by means of an iterative approach which generalizes the calculation of [7]. Since $\Delta_\pm(\hat{n}, \tau) = \Delta_Q(\hat{n}, \tau) \pm i \Delta_U(\hat{n}, \tau)$, it transforms as a spin ± 2 for rotations around a plane orthogonal to the direction of propagation of the radiation. The three-dimensional rotations and the rotations on the tangent plane of the sphere at a given point combine to give a $O(4)$ symmetry group [10]. Generalized ladder operators raising (or lowering) the spin weight of a given function can then be defined as [10, 11]:

$$K_\pm^s(\hat{n}) = -(\sin \vartheta)^{\pm s} \left[\partial_\vartheta \pm \frac{i}{\sin \vartheta} \partial_\varphi \right] (\sin \vartheta)^{\mp s}, \quad \hat{n} = (\vartheta, \varphi). \quad (12)$$

In real space the E-mode and the B-mode polarization will have spin weight $s = 0$:

$$\Delta_E(\hat{n}, \tau) = -\frac{1}{2} \{ K_-^{(1)}(\hat{n}) [K_-^{(2)}(\hat{n}) \Delta_+(\hat{n}, \tau)] + K_+^{(-1)}(\hat{n}) [K_+^{(-2)}(\hat{n}) \Delta_-(\hat{n}, \tau)] \}, \quad (13)$$

$$\Delta_B(\hat{n}, \tau) = \frac{i}{2} \{ K_-^{(1)}(\hat{n}) [K_-^{(2)}(\hat{n}) \Delta_+(\hat{n}, \tau)] - K_+^{(-1)}(\hat{n}) [K_+^{(-2)}(\hat{n}) \Delta_-(\hat{n}, \tau)] \}. \quad (14)$$

The heat transfer equation will then contain, in Fourier space, a convolution. Since the polarization is generated rather close to last scattering the iterative procedure of [7] implies that, to zeroth order in the rotation rate, the polarization is given, in real space, as

$$\Delta_P(\hat{n}, \tau) = \frac{1}{(2\pi)^{3/2}} \int d^3k \Delta_P(k, \mu, \tau_0), \quad S_P = \Delta_{P0} + \Delta_{P2} + \Delta_{I2}$$

³Different experiments are characterized by different channels of observations. For instance Quad [3] employs two series of bolometers located, respectively, at 100 GHz and at 150 GHz.

$$\Delta_P(k, \mu, \tau_0) = \frac{3}{4}(1 - \mu^2) \int_0^{\tau_0} \mathcal{K}(\tau) S_P(k, \tau) e^{-ik\mu(\tau - \tau_0)} d\tau, \quad (15)$$

where $\mathcal{K}(\tau)$ is the visibility function. In terms of $\Delta_P(\hat{n}, \tau)$, Eqs. (13) and (14) imply

$$\begin{aligned} \Delta_E(\hat{n}, \tau) &= -\partial_\mu^2 \{ \cos[2\psi(\hat{n}, \tau)] (1 - \mu^2) \Delta_P(\hat{n}, \tau) \}, \\ \Delta_B(\hat{n}, \tau) &= \partial_\mu^2 \{ \sin[2\psi(\hat{n}, \tau)] (1 - \mu^2) \Delta_P(\hat{n}, \tau) \}, \end{aligned} \quad (16)$$

where, as usual, $\mu = \cos \vartheta$ and ∂_μ denotes a derivation with respect to $\cos \vartheta$. In the absence of the (inhomogeneous) magnetized contribution Eq. (16) leads to the expressions customarily used in standard analyses, i.e. for instance

$$C_\ell^{(\text{BB})} = \sin^2 2\psi \overline{C}_\ell^{(\text{EE})}, \quad C_\ell^{(\text{EB})} = \frac{1}{2} \sin 4\psi \overline{C}_\ell^{(\text{EE})}, \quad C_\ell^{(\text{TB})} = \sin 2\psi \overline{C}_\ell^{(\text{TE})}, \quad (17)$$

where $\psi(\hat{n}, \tau) = \Phi_\sigma(\tau) \simeq \Phi_\sigma(\tau_0)$ is fully homogeneous and where the $\overline{C}_\ell^{(\text{EE})}$ and $\overline{C}_\ell^{(\text{TE})}$ are computed from $\Delta_P(\hat{n}, \tau)$. If also the magnetized contribution is taken into account the situation changes both qualitatively and quantitatively. This aspect can be understood from Eq. (16). In the limit of small rotation rate

$$\Delta_E(\hat{n}, \tau) = -\partial_\mu^2 [(1 - \mu^2) \Delta_P(\hat{n}, \tau)], \quad \Delta_B(\hat{n}, \tau) = 2 \partial_\mu^2 [\psi(\hat{n}, \tau) (1 - \mu^2) \Delta_P(\hat{n}, \tau)], \quad (18)$$

where $\psi(\hat{n}, \tau)$ and $\Delta_P(\hat{n}, \tau)$ depend upon the same point on the microwave sky. Eq. (18) holds in real space. In Fourier space the B-mode would be a convolution. In multipole space the angular power spectra inherit a peculiar form which contains a double sum involving also a known Wigner coefficient arising from the integral of three Legendre polynomials [7].

In Fig. 1 (plot at the left) the B-mode autocorrelations are reported in the case when the magnetized background competes with the pseudo-scalar background. The B-mode signal is frequency dependent. In the plot at the right the cross-correlations of the B-mode with the other CMB observables are illustrated. The observational frequency channel has been taken, for illustration, $\overline{\nu} = 100\text{GHz}$. In Fig. 1 B_L denotes the magnetic field intensity regularized over a the pivot length-scale $k_L^{-1} \simeq \text{Mpc}$. If the pseudo-scalar contribution is totally subleading the C_ℓ^{BB} angular power spectrum will diminish with the frequency as $\overline{\nu}^{-4}$. Still the cross-correlations of the B-mode with the temperature and the E-mode polarization (i.e. C_ℓ^{TB} and C_ℓ^{EB}) are non-vanishing. This aspect is illustrated in Fig. 1 (plot at the right) where C_ℓ^{TB} and C_ℓ^{EB} are reported. The numerical calculation leading to the results reported in Fig. 1 has been performed by including the magnetic field in the initial conditions and at every step of the Einstein-Boltzmann hierarchy and for the initial conditions corresponding to the magnetized adiabatic mode.

In summary, if observations point towards a frequency dependence of the B-mode polarization Faraday rotation is probably the only candidate. The cross-correlations (i.e. the EB and TB spectra) are expected to vanish in the case of a stochastic magnetic field leaving unbroken spatial isotropy [5]. If they are observed this means that the rotation rate is

quasi-homogeneous and a pseudo-scalar background field may be around. In the latter case, if $\overline{\omega} > \overline{\omega}_\sigma$ the B-mode will scale with frequency as dictated by the Faraday effect while the EB and TB correlations will allow to measure independently ω_σ . In the opposite case (i.e. $\overline{\omega} < \overline{\omega}_\sigma$) the frequency dependence induced by the Faraday effect is overwhelmed by the (homogeneous) pseudo-scalar rate. In this second case the effects of the primordial magnetic fields will be imprinted on the EE and TT angular power spectra [5, 6] but the B-mode autocorrelations will be independent of the frequency. This demonstrate that the analysis of the B-mode autocorrelation is necessary but might insufficient, if taken individually, to infer the existence of pre-decoupling magnetic fields.
